What are search problems?

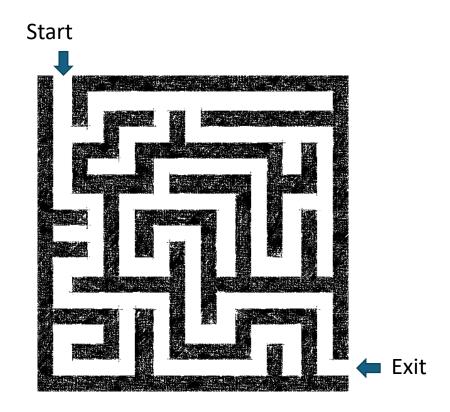

Tree search space

Search space

Uninformed search
search

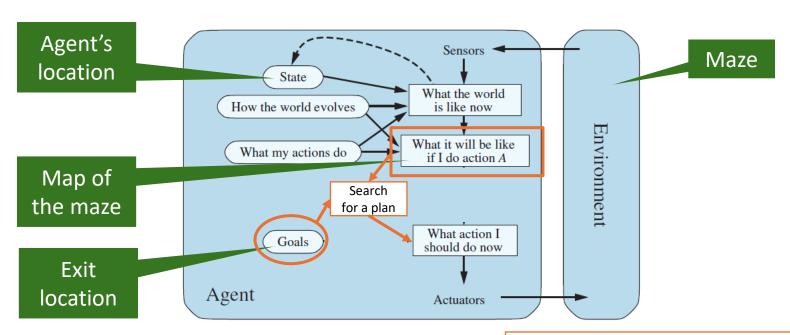

What are Search Problems?

- We will consider the problem of designing goal-based agents in known, fully observable, and deterministic environments.
- Example environment:

Remember: Goal-based Agent

- The agent has the task to reach a defined goal state.
- The performance measure is typically the cost to reach the goal.
- We will discuss a special type of goal-based agents called planning agents which
 use search algorithms to plan a sequence of actions that lead to the goal.

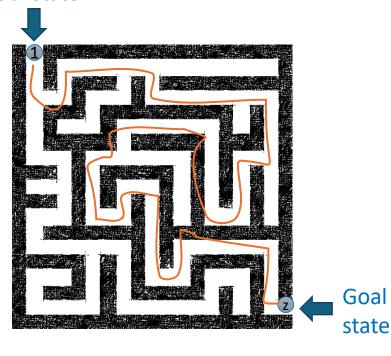

$$a_i = \operatorname{argmin}_{a_i \in A} \left[\sum_{t=i}^T c_t \mid s_T \in S^{goal} \right]$$

Planning for Search Problems

- For now, we consider only a discrete environment using an atomic state representation (states are just labeled 1, 2, 3, ...).
- The state space is the set of all possible states of the environment and some states are marked as goal states.
- The **optimal solution** is the sequence of actions (or equivalently a sequence of states) that gives the lowest path cost for reaching the goal.

Initial state

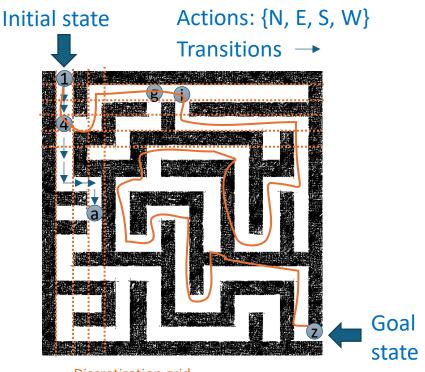

Phases:

- 1) Search/Planning: the process of looking for the sequence of actions that reaches a goal state. Requires that the agent knows what happens when it moves!
- 2) Execution: Once the agent begins executing the search solution in a deterministic, known environment, it can ignore its percepts (open-loop system).

Definition of a Search Problem

- Initial state: state description
- Actions: set of possible actions A
- Transition model: a function that defines the new state resulting from performing an action in the current state
- Goal state: state description
- Path cost: the sum of step costs

····· Discretization grid

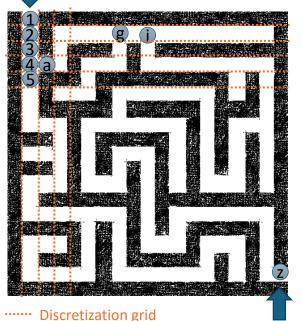

Important: The **state space** is typically too large to be enumerated, or it is continuous. Therefore, the problem is defined by initial state, actions and the transition model and not the set of all possible states.

Transition Function and Available Actions

Original Description

Initial state Actions: {N, E, S, W}

Transitions →

• Definition as an action schema:

Action(go(dir))

PRECOND: no wall in direction dir

EFFECT: change the agent's location according to dir

• Definition as a **function**:

$$f: S \times A \rightarrow S \text{ or } s' = result(s, a)$$

 A graph with states as vertices and actions as edges.

 Function implemented as a table representing the state space as a graph.

S	а	s'
1	S	2
2	N	1
2	S	3
4	Ε	а
4	E S	a 5
4	S	5

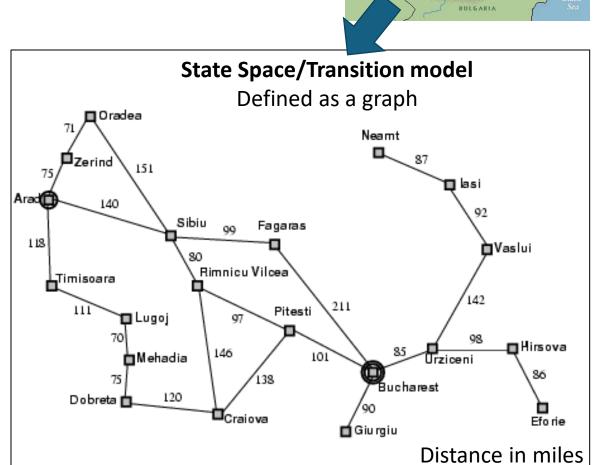

Available actions in a state come from the transition function. E.g.,
 actions(4) = {E,S,N}

Note: Known and deterministic is a property of the transition function!

Goal state

Example: Romania Vacation

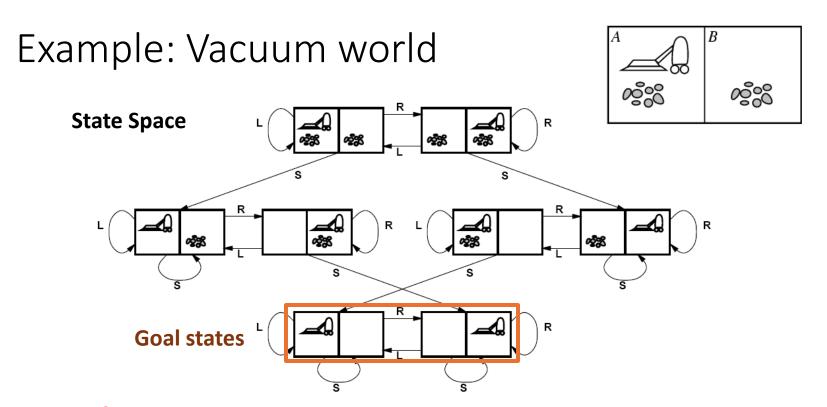

- On vacation in Romania; currently in Arad
- Flight leaves tomorrow from Bucharest
- Initial state: Arad
- Actions: Drive from one city to another.
- Transition model and states: If you go from city A to city B, you end up in city B.
- Goal state: Bucharest
- Path cost: Sum of edge costs.

YUGOSL

Original Description

BUCHARESI

- Initial State: Defined by agent location and dirt location.
- Actions: Left, right, suck
- Transition model: Clean a location or move.
- Goal state: All locations are clean.
- Path cost: E.g., number if actions

There are 8 possible atomic states of the system.

Why is the number of states for n possible locations $n(2^n)$?

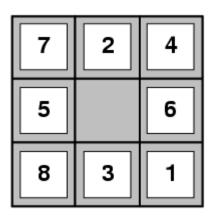

Example: Sliding-tile Puzzle

- Initial State: A given configuration.
- Actions: Move blank left, right, up, down
- Transition model: Move a tile
- Goal state: Tiles are arranged empty and 1-8 in order
- Path cost: 1 per tile move.

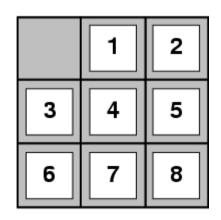

State space size

Each state describes the location of each tile (including the empty one). ½ of the permutations are unreachable.

- 8-puzzle: 9!/2 = 181,440 states
- 15-puzzle: $16!/2 \approx 10^{13}$ states
- 24-puzzle: $25!/2 \approx 10^{25}$ states

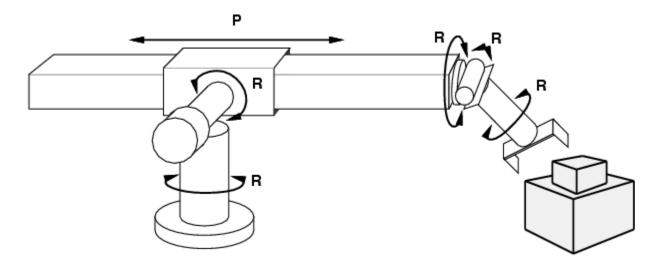

Start State

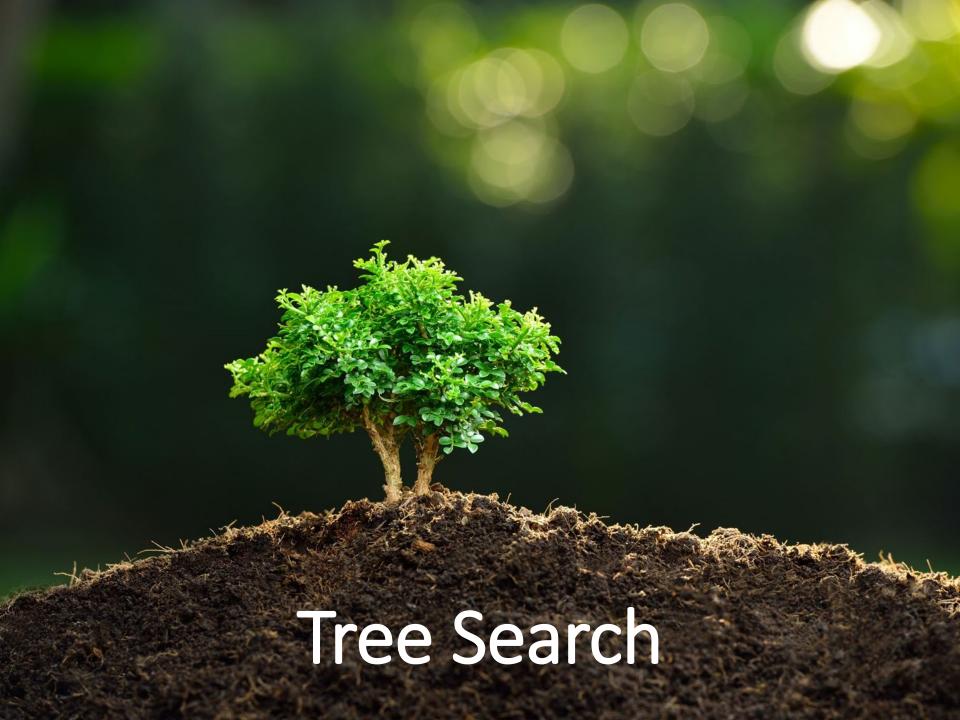

Goal State

Example: Robot Motion Planning

- Initial State: Current arm position with real-valued coordinates of robot joint angles.
- Actions: Continuous motions of robot joints.
- Transition model: Movement.
- Goal state: Desired final configuration (e.g., object is grasped).
- Path cost: Time to execute, smoothness of path, etc.

Solving Search Problems

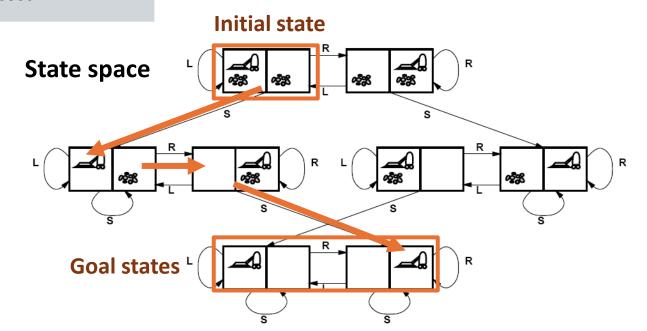

Given a search problem definition

- Initial state
- Actions
- Transition model
- Goal state
- Path cost

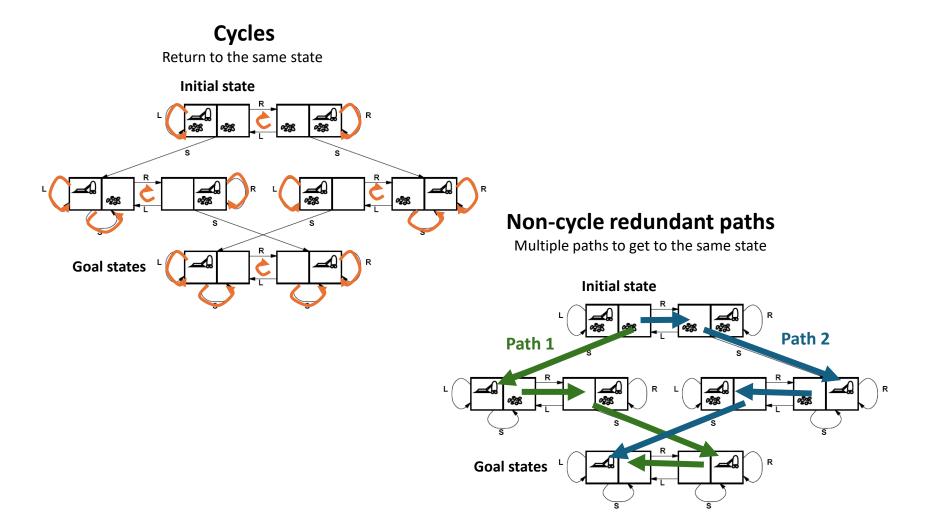

How do we find the optimal solution (sequence of actions/states)?

Construct a search tree for the state space graph!

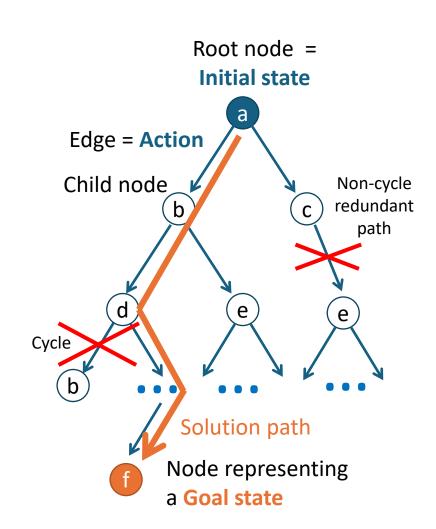

Issue: Transition Model is a Graph and Not a Tree!

Creating a Search Tree

- Superimpose a "what if" tree of possible actions and outcomes (states) on the state space graph.
- The Root node represents the initial stare.
- An action child node is reached by an edge representing an action. The corresponding state is defined by the transition model.
- Trees cannot have cycles (loops). Cycles in the search space must be broken to prevent infinite loops.
- Trees cannot have multiple paths to the same state. These are called redundant paths. Removing other redundant paths improves search efficiency.
- A path through the tree corresponds to a sequence of actions (states).
- A **solution** is a path ending in a node representing a goal state.
- Nodes vs. states: Each tree node represents a state of the system. If redundant path cannot be prevented then state can be represented by multiple nodes in the tree.

Differences Between Typical Tree Search and Al Search

Typical tree search

Assumes a given tree that fits in memory.

Trees have by construction no cycles or redundant paths.

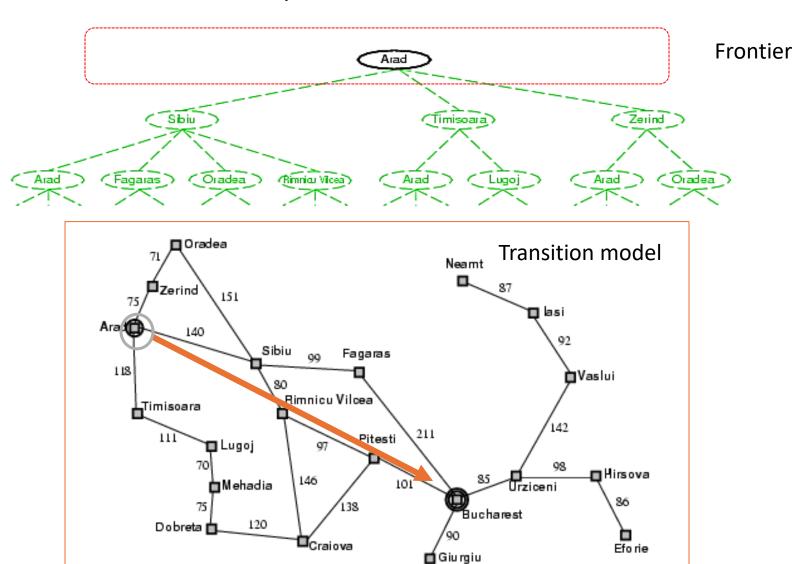

Al tree/graph search

- The search tree is too large to fit into memory.
 - **a. Builds parts of the tree** from the initial state using the transition function representing the graph.
 - **b.** Memory management is very important.
- The search space is typically a very large and complicated graph. Memory-efficient cycle checking is very important to avoid infinite loops or minimize searching parts of the search space multiple times.
- Checking redundant paths often requires too much memory and we accept searching the same part multiple times.

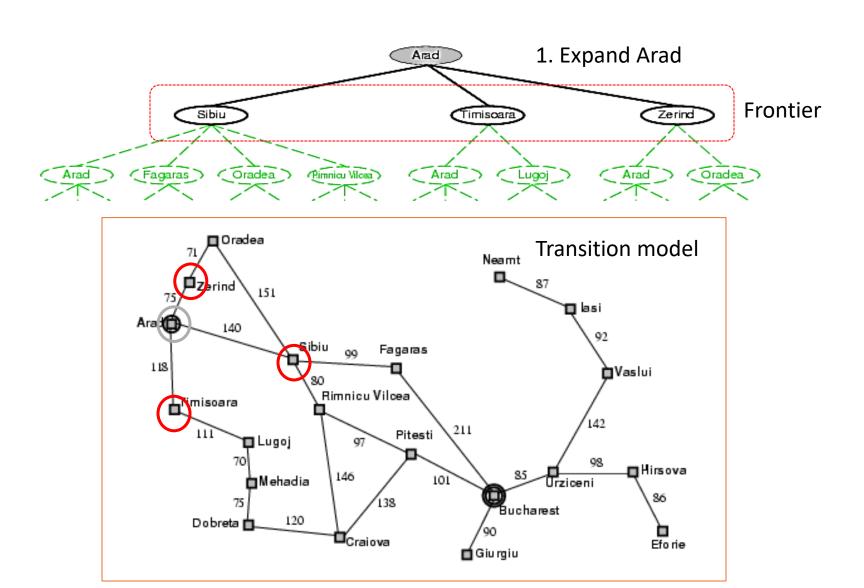

Tree Search Algorithm Outline

- 1. Initialize the **frontier** (set of unexplored known nodes) using the **starting state/root node**.
- 2. While the frontier is not empty:
 - a) Choose the next frontier node to expand according to the search strategy.
 - b) If the node represents a goal state, return it as the solution.
 - c) Else **expand** the node (i.e., apply all possible actions to the transition model) and add its children nodes representing the newly reached states to the frontier.

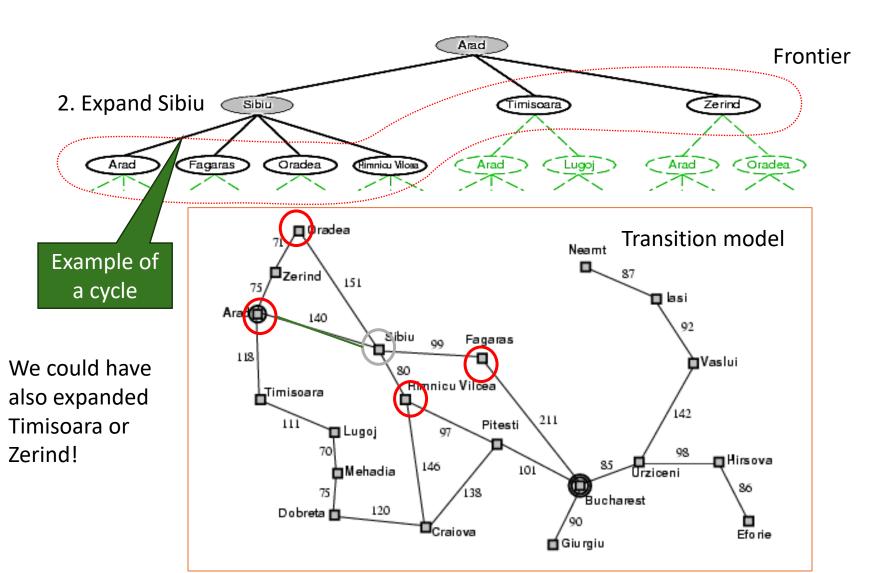

Tree Search Example

Tree Search Example

Tree Search Example

Search Strategies: Properties

- A search strategy is defined by picking the order of node expansion.
- Strategies are evaluated along the following dimensions:
 - Completeness: does it always find a solution if one exists?
 - Optimality: does it always find a least-cost solution?
 - Time complexity: how long does it take?
 - Space complexity: how much memory does it need?
- We will discuss different search strategies and use these properties to compare them.

Space and Time Complexity

State Space vs. Search Tree Size

State Space vs. Search Tree Size

• Space and time complexity depend on the **number of tree nodes** searched (created and visited) till a goal node is found. For a tree with n nodes we have:

O(n)

• **Remember**: For perfect cycle checking and redundant path elimination, we have a 1:1 mapping between nodes and states:

Nodes in the search tree = states in the search space Otherwise, we may have multiple nodes representing a state.

- We have the following options to estimate *n* for a search problem:
 - a. Estimate the reachable state space size.
 - b. Estimate the number of searched tree nodes.
- Estimating the complexity is important to judge:
 - How difficult is the problem?
 - What algorithm will fit in memory?
 - Can we find a solution fast enough?
 - Can we find the optimal solution, or do we need to use a heuristic?

State Space Size Estimation

State Space

- Number of different states the agent and environment can be in.
- Reachable states are defined by the initial state and the transition model. Only reachable states are important for search.

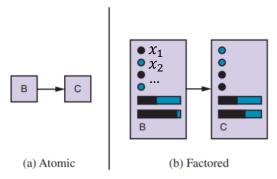

Estimation

- Even if the used algorithm represents the state space using atomic states, we may know the internal (factored) representation. It can be used to estimate the problem size.
- The basic rule is to estimate the state space size for factored state representation with l fluents (variables) as:

$$n = |X_1| \times |X_2| \times \cdots \times |X_l|$$

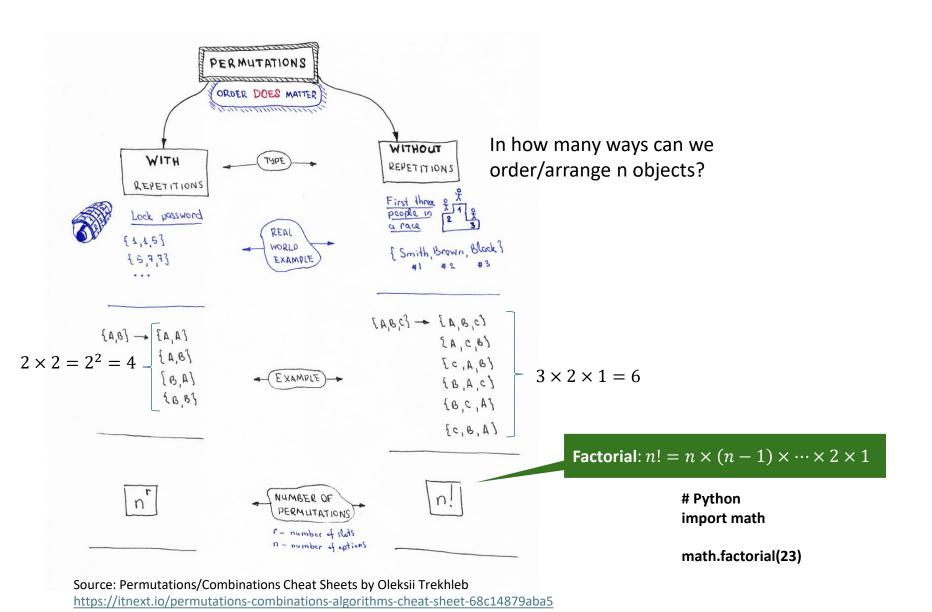

where $|\cdot|$ is the number of possible values.

State representation

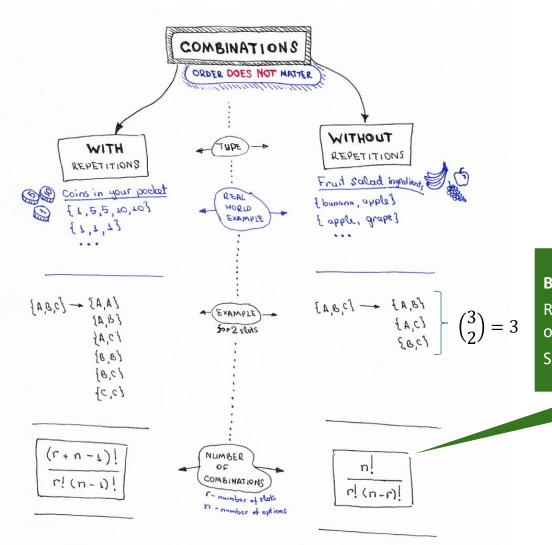

The factored state consists of variables called fluents that represent conditions that can change over time.

Reminder: Combinatorics - Permutations

Reminder: Combinatorics - Combinations

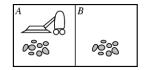

Binomial Coefficient: $\binom{n}{r} = C(n,r) = {}_{n}C_{r}$ Read as "n choose r" because it is the number of ways can we choose r out of n objects? Special case for r=2: $\binom{n}{2}=\frac{n(n-1)}{2}$

Python import scipy.special

the two give the same results scipy.special.binom(10, 5) scipy.special.comb(10, 5)

Example: What is the State Space Size?

Dirt

- **Permutation:** A and B are different rooms, order does matter!
- With repetition: Dirt can be in both rooms.
- There are 2 options (clean/dirty)

$\rightarrow 2^2$

Robot location

Can be in 1 out of 2 rooms.

$$\rightarrow 2$$

Total: $n = 2 \times 2^2 = 2^3 = 8$

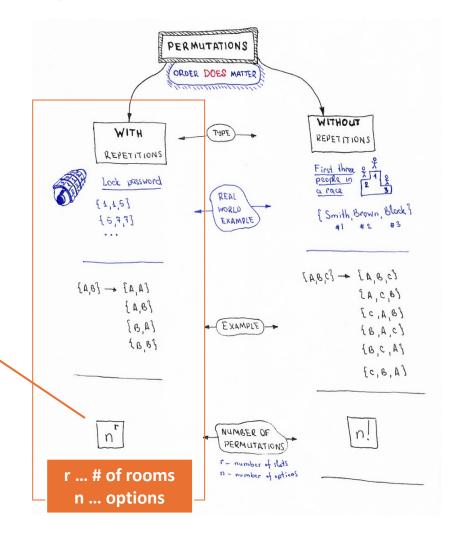

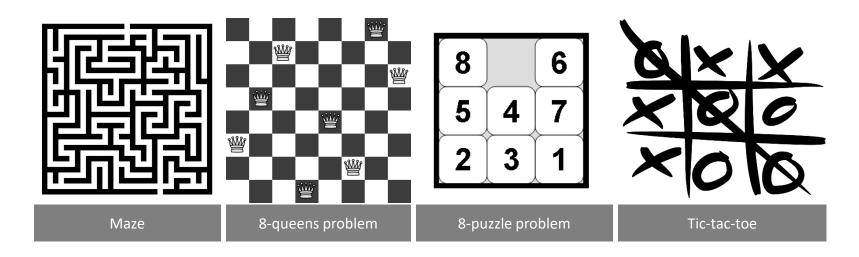

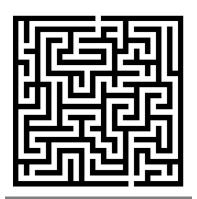

Examples: What is the State Space Size?

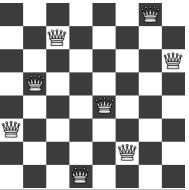

Often a rough upper limit is sufficient to determine how hard the search problem is.

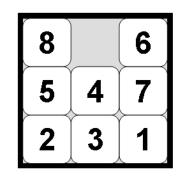

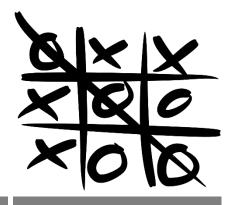

Examples: What is the State Space Size?

Often a rough upper limit is sufficient to determine how hard the search problem is.

Maze

8-queens problem

8-puzzle problem

Tic-tac-toe

Positions the agent can be in.

n = Number of white squares.

Action: Move one queen at a time

All arrangements with 8 queens on the board.

$$n < 2^{64} \approx 1.8 \times 10^{19}$$

We only have 8 queens: $n = \binom{64}{9} \approx 4.4 \times 10^9$

All arrangements of 9 elements.

$$n \leq 9!$$

Half is unreachable:

$$n = \frac{9!}{2} = 181,440$$

All possible boards.

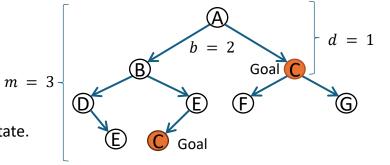

$$n < 3^9 = 19,683$$

Many boards are not legal (e.g., all x's)

The actual number can be obtained by a depth-first traversal of the game tree.

Estimating the Search Tree Size

- Instead of estimating the state space size, it is often more useful to estimate the number of searched nodes in the search tree.
- This is especially important when **redundant paths are not eliminated**, where one state can be represented by multiple nodes.
- We can base the estimation on the search problem description:
 - initial state
 - Actions
 - · transition function.
- Used metrics are:
 - *b*: maximum branching factor of the search tree max. number of available actions.
 - m: maximal tree depth length of the longest path with loops removed.
 - d: depth of the optimal solution min. length of the path from the initial state to a solution state.

• The number of searched nodes is then a function of b, m and d.

$$n = f(b, m, d) \Rightarrow O(f(b, m, d))$$

Example: What is the Search Complexity?

b: maximum branching factor = max. number of available actions?

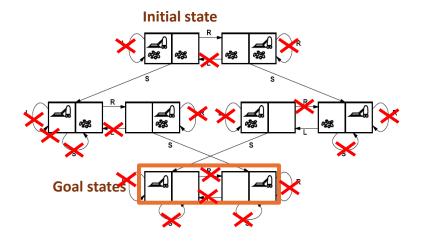

3

• m: the number of actions in longest path? Without loops!

4

• *d*: min. depth of the optimal solution?

State Space with Transition Model

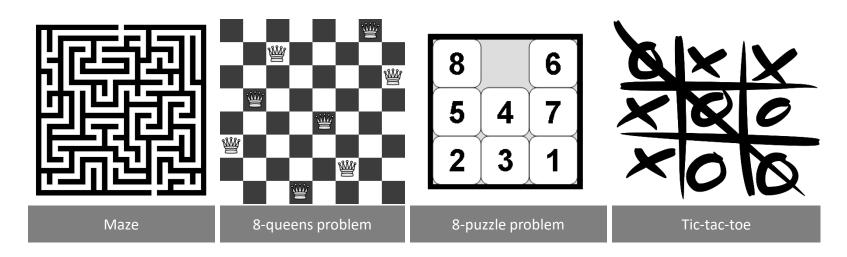

Make sure it is a tree!

Examples: What is the Search Complexity?

b: maximum branching factorm: max. depth of treed: depth of the optimal solution

Often a rough upper limit is sufficient to determine how hard the search problem is.

h =

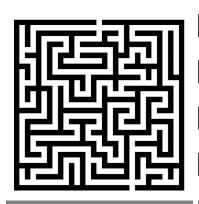

m =

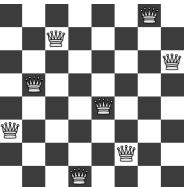

d =

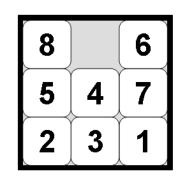

Examples: What is the Search Complexity?

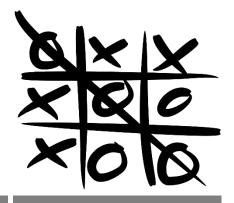

b: maximum branching factorm: max. depth of treed: depth of the optimal solution

Often a rough upper limit is sufficient to determine how hard the search problem is.

Maze

b = 4 actions

m = longest path to thegoal or a dead end (bounded by $x \times y$)

d = shortest path to the goal (bounded by $x \times y$)

8-queens problem

Action: Move one queen at a time

 $b = 8 \times (64 - 8) = 448$

m = We may have to try all: $\binom{64}{9} \approx 4.4 \times 10^9$

d = move each queen in the right spot = 8

8-puzzle problem

b = 4 actions to move the empty tile.

m = Try all O(9!)

d = ??? We need to solve the problem to know.

Tic-tac-toe

b = 9 actions for the first move.

m = 9

d = 9 (if both play optimal)

Uninformed Search Strategies

The search algorithm/planning agent is **not provided with information about how close a state is to the goal state**.

It only uses the labels of the atomic states and the transition function.

It blindly searches, following a simple strategy, until it reaches the goal state.

Search strategies:

- Breadth-first search strategy: BFS and uniform-cost search
- **Depth-first search strategy**: DFS and Iterative deepening search

Breadth-First Search (BFS)

Expansion rule: Expand shallowest unexpanded node in the frontier (=**FIFO**).

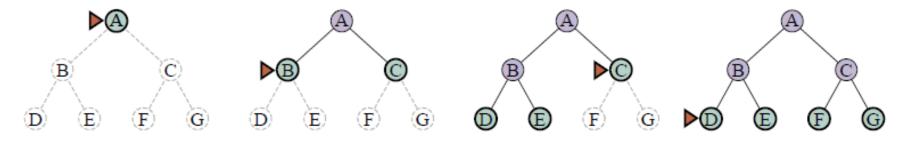

Figure 3.8 Breadth-first search on a simple binary tree. At each stage, the node to be expanded next is indicated by the triangular marker.

Data Structures

- **Frontier** data structure: holds references to the green nodes (green) and is implemented as a FIFO **queue**.
- Reached data structure: holds references to all visited nodes (gray and green) and is
 used to prevent visiting nodes more than once (cycle and redundant path checking).
- Builds a complete tree with links between parent and child.

Implementation: Breadth-First Search

```
function BREADTH-FIRST-SEARCH(problem) returns a solution node or failure
  node \leftarrow \text{NODE}(problem.\text{INITIAL})
  if problem.IS-GOAL(node.STATE) then return node
  frontier \leftarrow a FIFO queue, with node as an element
  reached \leftarrow \{problem.INITIAL\}
   while not IS-EMPTY(frontier) do
     node \leftarrow POP(frontier)
     for each child in EXPAND(problem, node) do
       s \leftarrow child.STATE
       if problem.IS-GOAL(s) then return child
       if s is not in reached then -
          add s to reached
          add child to frontier
  return failure
```

Expand adds the next level below node to the frontier.

reached makes sure we do not visit nodes twice (e.g., in a cycle or other redundant path). Fast lookup is important.

Implementation: Expanding the Search Tree

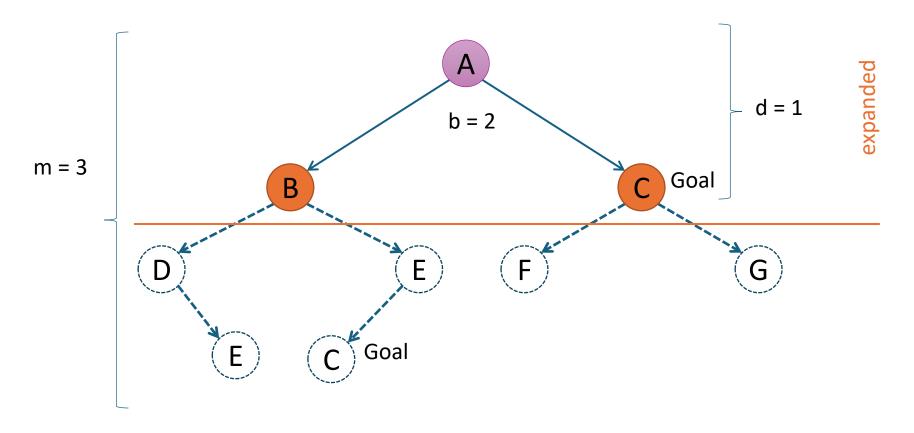

- Al tree search creates the search tree while searching.
- The EXPAND function tries all available actions in the current node using the **transition function** (RESULTS).
- It returns a list of child nodes for the frontier.

```
\begin{array}{l} \textbf{function EXPAND}(\textit{problem}, node) \ \textbf{yields} \ \text{nodes} \\ s \leftarrow node. \text{STATE} \\ \textbf{for each } \textit{action in } \textit{problem}. \text{ACTIONS}(s) \ \textbf{do} \\ s' \leftarrow \textit{problem}. \text{RESULT}(s, action) \\ cost \leftarrow node. \text{PATH-COST} + \textit{problem}. \text{ACTION-COST}(s, action, s') \\ \textbf{yield NODE}(\text{STATE} = s', \text{PARENT} = node, \text{ACTION} = action, \text{PATH-COST} = cost) \\ \end{array}
```

Yield (generator function) can also be implemented by returning a list of nodes.

Time and Space Complexity Breadth-First Search

d: depth of the optimal solutionm: max. depth of treeb: maximum branching factor

All paths to the depth of the goal are expanded. The search tree size is $1 + b + b^2 + ... + b^d \Rightarrow O(b^d)$

Properties of Breadth-First Search

Complete?

Yes

d: depth of the optimal solutionm: max. depth of treeb: maximum branching factor

Optimal?

Yes – if cost is the same per step (action). Otherwise: Use uniform-cost search.

Time?

Number of nodes created: $O(b^d)$

Space?

Stored nodes: $O(b^d)$

Note:

In AI, the large space complexity is usually a bigger problem than time!

Uniform-cost Search (= Dijkstra's Shortest Path Algorithm)

- Expansion rule: Expand node in the frontier with the least path cost from the initial state.
- Implementation: **best-first search** where the frontier is a **priority queue** ordered by lower f(n) = **path cost** (cost of all actions starting from the initial state).
- Breadth-first search is a special case when all step costs being equal, i.e., each action costs the same!

Complete?

Yes, if all step cost is greater than some small positive constant $\varepsilon > 0$

d: depth of the optimal solutionm: max. depth of treeb: maximum branching factor

Optimal?

Yes – nodes expanded in increasing order of path cost

Time?

Expands all nodes with path cost $c \leq C^*$ (cost of optimal solution) leading to $O(b^{1+C^*/\epsilon})$ for the number of nodes.

Note: This can be greater than BFS's $O(b^d)$: the search can explore long paths consisting of small steps before exploring shorter paths consisting of larger steps.

Space?

 $O(b^{1+C^*/\varepsilon})$

See Dijkstra's algorithm on Wikipedia

Implementation: Best-First Search Strategy

Note: This generalizes Breadth-First-Search

function UNIFORM-COST-SEARCH(problem) **returns** a solution node, or failure **return** BEST-FIRST-SEARCH(problem, PATH-COST)

```
function BEST-FIRST-SEARCH(problem, f) returns a solution node or failure
  node \leftarrow Node(State = problem.INITIAL)
  frontier \leftarrow a priority queue ordered by f, with node as an element
  reached \leftarrow a lookup table, with one entry with k = problem. INITIAL and value node
  while not IS-EMPTY(frontier) do
                                                                           The order for expanding the
     node \leftarrow Pop(frontier)
                                                                             frontier is determined by
     if problem.IS-GOAL(node.STATE) then return node
                                                                             f(n) = path cost from the
     for each child in EXPAND(problem, node) do
                                                                               initial state to node n.
       s \leftarrow child.STATE
       if s is not in reached or child. PATH-COST < reached[s]. PATH-COST then
          reached[s] \leftarrow child
          add \mathit{child} to \mathit{frontier}
  return failure
                                                                           This check is added to BFS! It
```

See BFS for function EXPAND.

This check is added to BFS! It visits a node again if it can be reached by a better (cheaper) path.

Depth-First Search (DFS)

- **Expansion rule:** Expand deepest unexpanded node in the frontier (last added).
- Frontier: stack (LIFO)
- No reached data structure!

Cycle checking checks only the current path.

Redundant paths can not be identified and lead to replicated work.

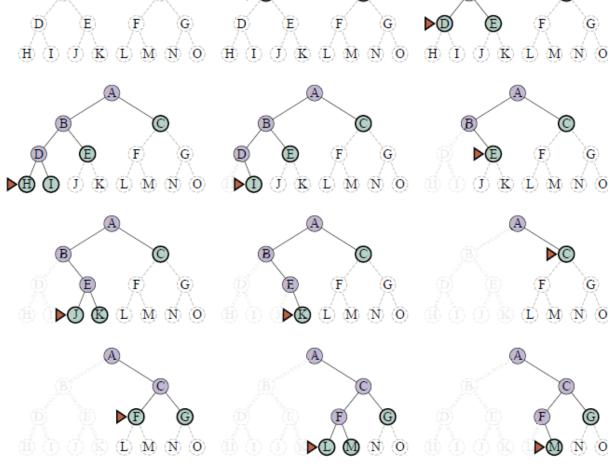

Figure 3.11 A dozen steps (left to right, top to bottom) in the progress of a depth-first search on a binary tree from start state A to goal M. The frontier is in green, with a triangle marking the node to be expanded next. Previously expanded nodes are lavender, and potential future nodes have faint dashed lines. Expanded nodes with no descendants in the frontier (very faint lines) can be discarded.

Implementation: DFS

- DFS could be implemented like BFS/Best-first search, just taking the last element from the frontier (LIFO). However, to reduce the space complexity to O(bm), no reached data structure can be used!
- Options:
 - **Iterative implementation**: Build the tree, and abandoned branches are removed from memory. Cycle checking is only done against the current path. This is similar to Backtracking search.
 - Recursive implementation: Cycle checking is an issue because the current path is stored in the function call stack, which is not accessible to the function. An additional data structure that contains the nodes in the current path can be used.

function DEPTH-LIMITED-SEARCH(problem, ℓ) **returns** a node or failure or cutoff $frontier \leftarrow$ a LIFO queue (stack) with NODE(problem.INITIAL) as an element $result \leftarrow failure$ while not IS-EMPTY(frontier) do $node \leftarrow POP(frontier)$ **if** problem.IS-GOAL(node.STATE) **then return** node if DEPTH(node) > ℓ then $result \leftarrow cutoff$ else if not IS-CYCLE(node) do for each child in EXPAND(problem, node) do add *child* to *frontier* return result

Memory management: remove nodes for abandoned branches here!

DFS uses $\ell = \infty$

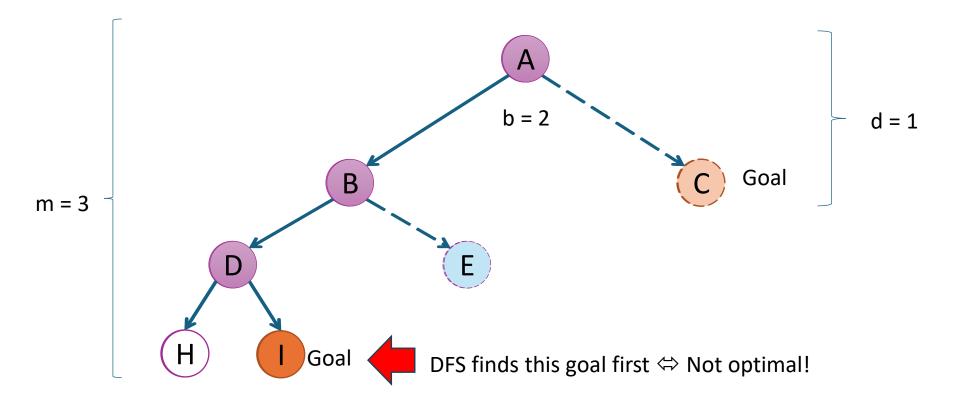

Cycles: Prevent cycles by checking against the current path. We also need to ensure that the frontier does not contain the same state more than once.

Redundant paths: We cannot prevent other redundant paths.

See BFS for function EXPAND.

Time and Space Complexity Depth-First Search

d: depth of the optimal solutionm: max. depth of treeb: maximum branching factor

- Time: $O(b^m)$ worst case is expanding all paths.
- Space: O(bm) if it only stores the frontier nodes and the current path.

Properties of Depth-First Search

Complete?

- In finite search spaces, cycles are avoided by checking for repeated states along the path.
- **Incomplete in infinite search spaces** (e.g., with cycles).

Optimal?

No – returns the first solution it finds.

d: depth of the optimal solutionm: max. depth of treeb: maximum branching factor

Time?

The worst case is to reach a solution at maximum depth m in the last path: $O(b^m)$ Terrible compared to BFS if $m \gg d$.

Space?

O(bm) is **linear in max. tree depth m** which is very good but only achieved if **no reached data structure and memory management** is used!

Cycles can be broken but redundant paths cannot be checked.

Iterative Deepening Search (IDS)

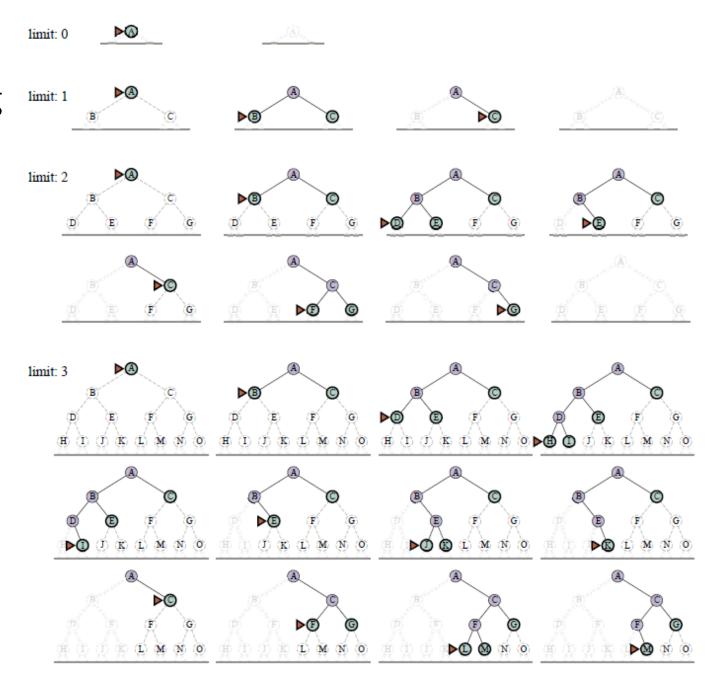

Can we

- get DFS's good memory footprint,
- · avoid infinite cycles, and
- preserve BFS's optimality guaranty?

Use depth-restricted DFS and gradually increase the depth.

- 1. Check if the root node is the goal.
- 2. Do a DFS searching for a path of length 1
- 3. If goal not found, do a DFS searching for a path of length 2
- 4. If goal not found, do a DFS searching for a path of length 3
- 5. ...

Iterative
Deepening
Search
(IDS)

Implementation: IDS

```
\begin{aligned} \textbf{function} & \text{ ITERATIVE-DEEPENING-SEARCH}(\textit{problem}) \textbf{ returns} \text{ a solution node or } \textit{failure} \\ & \textbf{for } \textit{depth} = 0 \textbf{ to} \propto \textbf{do} \\ & \textit{result} \leftarrow \text{DEPTH-LIMITED-SEARCH}(\textit{problem}, \textit{depth}) \\ & \textbf{if } \textit{result} \neq \textit{cutoff} \textbf{ then return } \textit{result} \end{aligned}
```

```
function DEPTH-LIMITED-SEARCH(problem, \ell) returns a node or failure or cutoff frontier \leftarrow a LIFO queue (stack) with Node(problem.Initial) as an element result \leftarrow failure while not Is-EMPTY(frontier) do node \leftarrow POP(frontier) if problem.Is-GOAL(node.STATE) then return node if DEPTH(node) > \ell then result \leftarrow cutoff else if not Is-CYCLE(node) do for each child in EXPAND(problem, node) do add child to frontier return result
```

See BFS for function EXPAND.

Properties of Iterative Deepening Search

Complete?

Yes

d: depth of the optimal solutionm: max. depth of treeb: maximum branching factor

Optimal?

Yes, if step cost = 1 (like BFS)

Time?

Consists of rebuilding trees up to d times $db + (d-1)b^2 + ... + 1b^d = O(b^d) \Leftrightarrow$ Slower than BFS, but the same complexity class!

Space?

 $O(bd) \Leftrightarrow$ linear space. Even less than DFS since $m \leq d$. Cycles need to be handled by the depth-limited DFS implementation.

Note: IDS produces the same result as BFS but trades **much better space complexity** for worse run time.

This makes IDS/DFS the workhorse of AI.

Informed Search

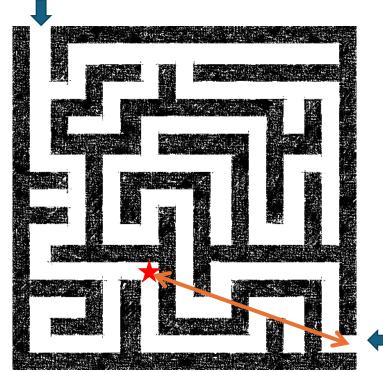

- Al search problems typically have a very large search space. We would like to improve efficiency by expanding as few nodes as possible.
- The agent can use additional information in the form of "hints" about what promising states are to explore first. These hints are derived from
 - information the agent has (e.g., a map with the goal location marked) or
 - percepts coming from a sensor (e.g., a GPS sensor and coordinates of the goal).
- The agent uses a heuristic function h(n) to rank nodes in the frontier and always select the most promising node in the frontier for expansion using the best-first search strategy.
- Discussed algorithms:
 - Greedy best-first search
 - A* search

Heuristic Function

- Heuristic function h(n) estimates the cost of reaching a node representing the goal state from the current node n.
- Examples:

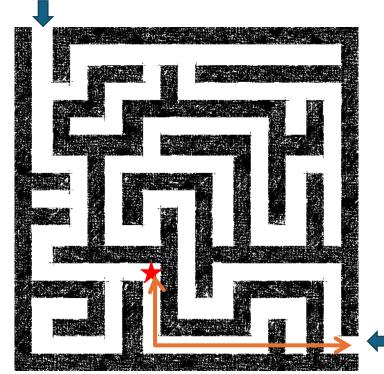

Euclidean distance

Start state

Manhattan distance

Start state

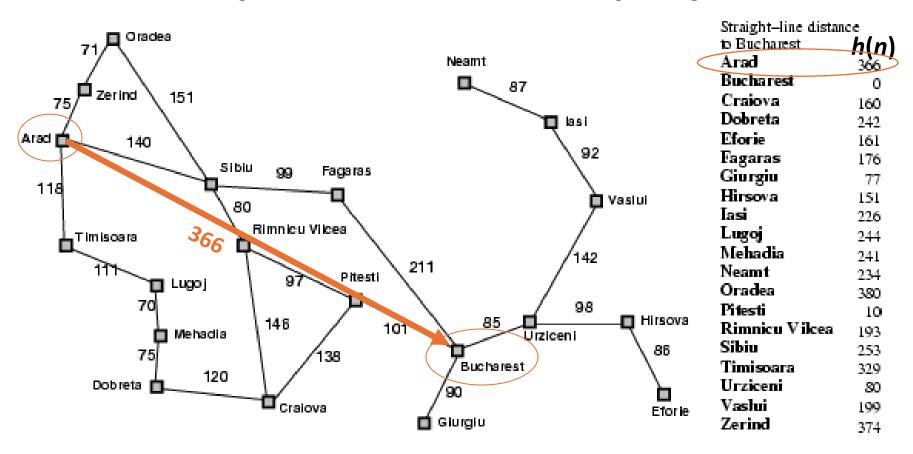

Goal state

Goal state

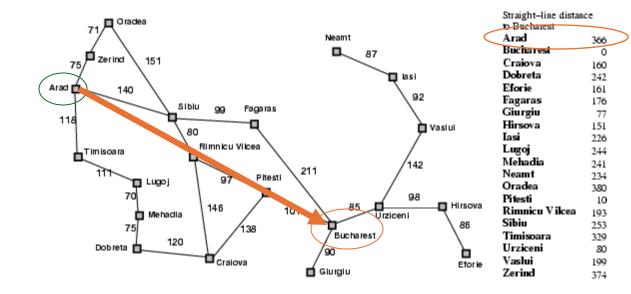

Heuristic for the Romania Problem

Implementation of Greedy Best-First search

Implementation of Greedy Best-First Search

Heuristic h(n) so we expand the node with the lowest estimated cost

```
function BEST-FIRST-SEARCH(problem, f) returns a solution node or failure
  node \leftarrow Node(State=problem.INITIAL)
  frontier \leftarrow a priority queue ordered by f, with node as an element
  reached \leftarrow a lookup table, with one entry with k = problem. INITIAL and value node
  while not IS-EMPTY(frontier) do
                                                                         The order for expanding the
     node \leftarrow Pop(frontier)
    if problem.IS-GOAL(node.STATE) then return node
                                                                           frontier is determined by
     for each child in EXPAND(problem, node) do
                                                                                       f(n)
       s \leftarrow child.STATE
       if s is not in reached or child. PATH-COST < reached[s]. PATH-COST then
          reached[s] \leftarrow child
          add child to frontier
  return failure
```

See BFS for function EXPAND.

d: depth of the optimal solutionm: max. depth of treeb: maximum branching factor

Time?

Worst case: $O(b^m) \Leftrightarrow \text{like DFS}$ Best case: O(bm) - If h(n) is 100% accurate we only expand a single path.

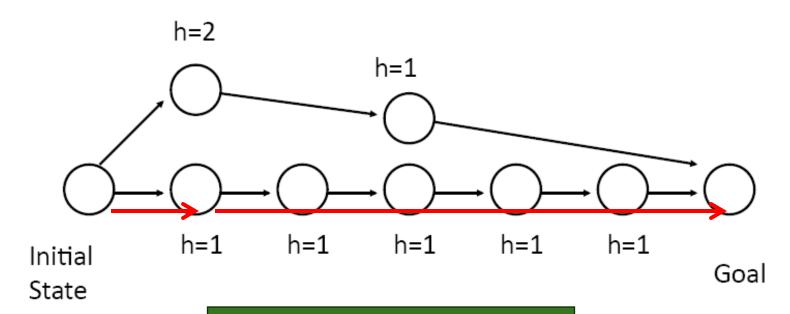

Space?

Same as time complexity.

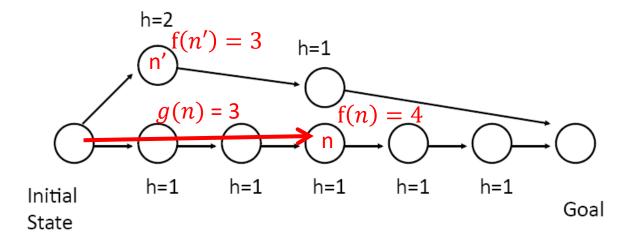

The Optimality Problem of Greedy Best-First search

Greedy best-first search only considers the estimated cost to the goal.

h=1 is better than h=2. Greedy best-first will go this way and never reconsider!

A* Search

- **Idea**: Take the cost of the path to n called g(n) into account to avoid expanding paths that are already very expensive.
- The evaluation function f(n) is the estimated total cost of the path through node n to the goal:

$$f(n) = g(n) + h(n)$$

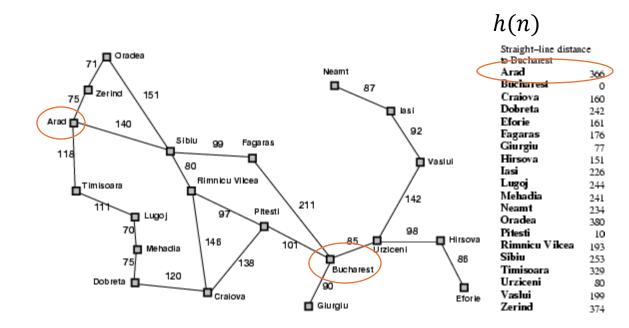

g(n): cost so far to reach n (path cost)

h(n): estimated cost from n to goal (heuristic)

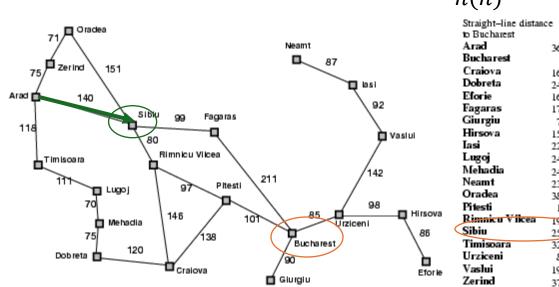

• The agent in the example above will stop at n with f(n) = 3 + 1 = 4 and chose the path up with a better f(n') = 1 + 2 = 3.

Note: For greedy best-first search we just used f(n) = h(n).

Expansion rule: $f(n) = g(n) + h(n) = \frac{A_{\text{rad}}}{366 = 0 + 366}$ Expand the node with the smallest f(n)

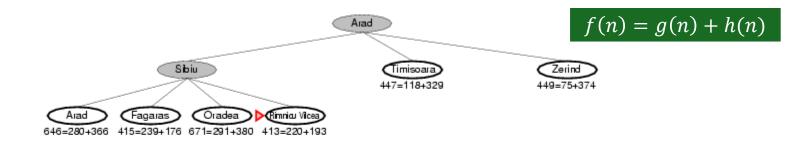

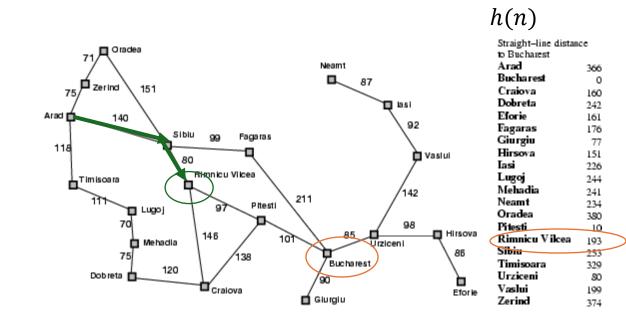

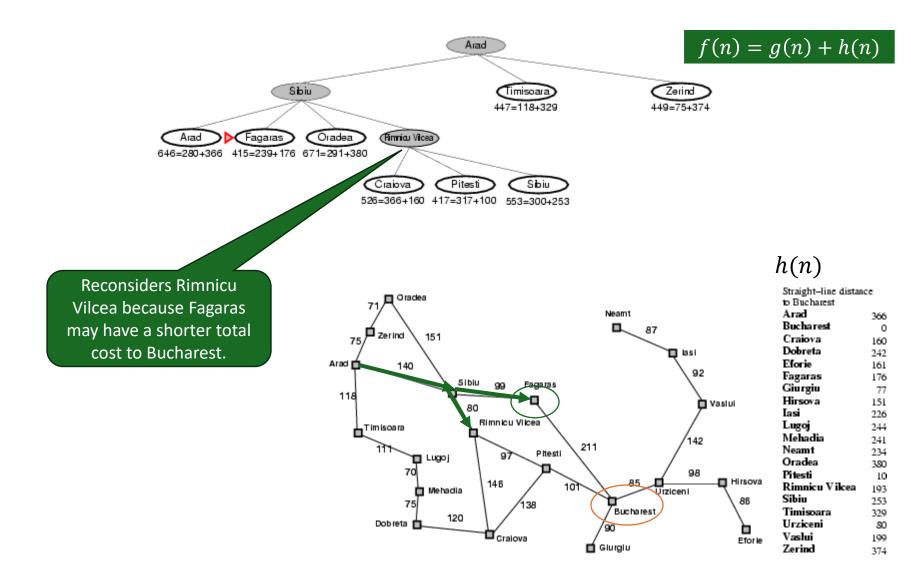

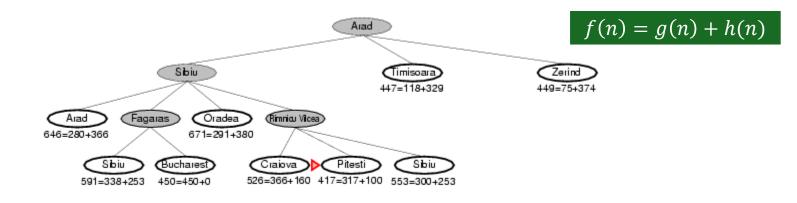

h(n)

BFS vs. A* Search

A* Search expands fewer nodes than BFS!

Implementation of A* Search

Path cost to n + heuristic from n to goal = estimate of the total cost g(n) + h(n)

```
function BEST-FIRST-SEARCH(problem, f) returns a solution node or failure
  node \leftarrow \texttt{NODE}(\texttt{STATE=}problem.\texttt{INITIAL})
  frontier \leftarrow a priority queue ordered by f, with node as an element
  reached \leftarrow a lookup table, with one entry with k \in problem. INITIAL and value node
  while not IS-EMPTY(frontier) do
                                                                             The order for expanding the
     node \leftarrow Pop(frontier)
                                                                              frontier is determined by
     if problem.IS-GOAL(node.STATE) then return node
                                                                                          f(n)
     for each child in EXPAND(problem, node) do
       s \leftarrow child.STATE
       if s is not in reached or child.PATH-COST < reached[s].PATH-COST then
          reached[s] \leftarrow child
          add child to frontier
  return failure
```

See BFS for function EXPAND.

Optimality: Admissible Heuristics

Definition: A heuristic h is **admissible** if for every node n, $h(n) \le h^*(n)$, where $h^*(n)$ is the true cost to reach the goal state from n.

I.e., an admissible heuristic is a **lower bound** and never overestimates the true cost to reach the goal.

Example: Straight line distance never overestimates the actual road distance.

Theorem: If h is admissible, A^* is optimal.

Guarantees of A* Search

A* is **optimally efficient**

No other tree-based search algorithm that employs the same heuristic can expand fewer nodes and still guarantee the optimal solution.

Proof: Any algorithm that does not expand all nodes with $f(n) < C^*$ (the lowest cost of going to a goal node) cannot be optimal. It risks missing the optimal solution.

Properties of A*Search

Complete?Yes

Optimal?

Yes

Time?

Number of nodes for which $f(n) \leq C^*$ in the worst case $O(b^d)$ like BFS.

Space?

Same as time complexity. This is often too high unless a very good heuristic is know.

Iterative-Deepening A* Search — IDA*

- Idea: A* search without a reached data structure.
- **Remember**: Regular IDA is uninformed and increases the cutoff by one after each iteration.
- IDA* uses the cost f=g+h of a node as the cutoff. In each iteration, the cost cutoff increases slightly. It is optimal if steps are small and h is admissible.

Issues:

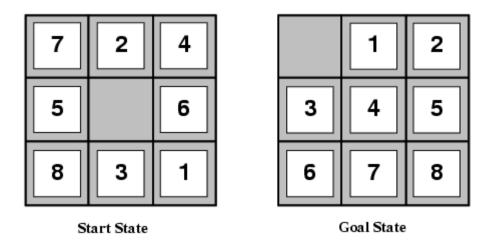

- By how much to increase the cutoff in each iteration.
- Rebuilds the tree many times.

Other memory-bounded variants of A* search:

- Recursive best-first search (RBFS) adds a f-limit to the depth-first search behavior of best-first search.
- Simplified memory-bounded A^* (SMA*) performs A^* till the memory is full and then drops the worst (highest f) leaf node from memory. It can rebuild the node later if needed.

Designing Heuristic Functions

Example heuristics for the 8-puzzle:

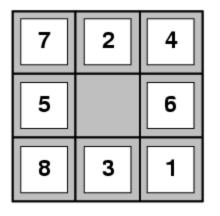

- $h_1(n)$ = number of misplaced tiles
- $h_1(start) = 8$
- $h_2(n)$ = total Manhattan distance (number of squares from the desired location of each tile)

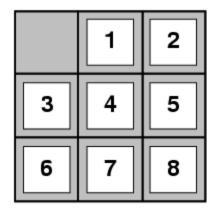

•
$$h_2(start) = 3 + 1 + 2 + 2 + 2 + 3 + 3 + 2 = 18$$

1 needs to move 3 positions

Heuristics from Relaxed Problems

- A problem with fewer restrictions on the actions is called a relaxed problem.
- The cost of an optimal solution to a relaxed problem is an admissible heuristic for the original problem. I.e., the true cost is never smaller.
- What relaxation is used by h_1 and h_2 ?
 - h_1 : If the rules of the 8-puzzle are relaxed so that a tile can move anywhere, then $h_1(n)$ gives the shortest solution.
 - h_2 : If the rules are relaxed so that a tile can move to any adjacent square, then $h_2(n)$ gives the shortest solution.

$$h_1(start) = 8$$

$$h_2(start)$$

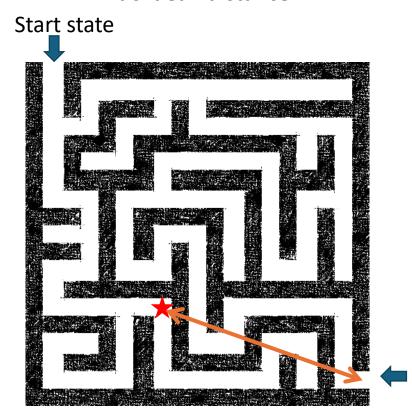

= 3 + 1 + 2 + 2 + 2 + 3 + 3 + 2
= 18

Start State Goal State

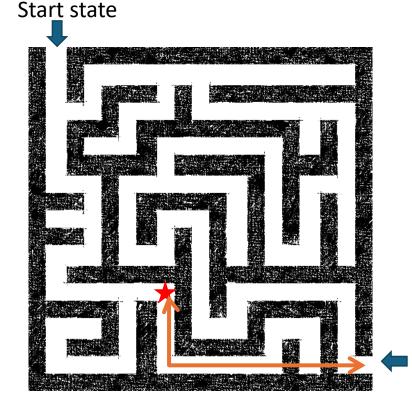

Heuristics from Relaxed Problems

What relaxations are used in these two cases?

Euclidean distance

Manhattan distance

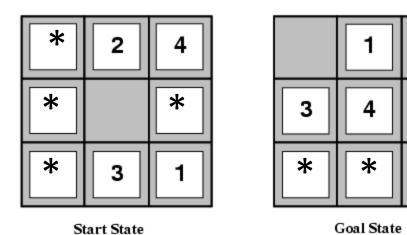

Goal state

Goal state

Heuristics from Subproblems

- Let $h_3(n)$ be the cost of getting a subset of tiles (say, 1,2,3,4) into their correct positions. The final order of the * tiles does not matter.
- Solutions for subproblems are an admissible heuristic.
- Calculation:
 - Very small subproblems are often easy to solve.
 - We can precompute and save the exact solution cost for every or many possible subproblem instances *pattern database*.

Dominance: What Heuristic is Better?

Definition: If h_1 and h_2 are both admissible heuristics and $h_2(n) \ge h_1(n)$ for all n, then h_2 dominates h_1

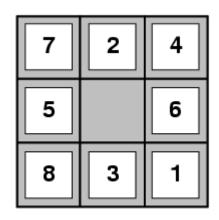

Is h_1 or h_2 better for A* search?

- A* search expands every node with $f(n) < C^* \Leftrightarrow h(n) < C^* g(n)$
- h_2 is never smaller than h_1 . A* search with h_2 will expand less nodes and is therefore better.

Example: Effect of Information in Search

Typical search costs for the 8-puzzle

• Solution at depth d=12IDS = 3,644,035 nodes $A^*(h_1) = 227$ nodes $A^*(h_2) = 73$ nodes

• Solution at depth d = 24IDS $\approx 54,000,000,000$ nodes A* $(h_1) = 39,135$ nodes A* $(h_2) = 1,641$ nodes

Combining Heuristics

- Suppose we have a collection of admissible heuristics h_1, h_2, \dots, h_m , but none of them dominates the others.
- Combining them is easy:

$$h(n) = \max\{h_1(n), h_2(n), ..., h_m(n)\}$$

• That is, always pick for each node the heuristic that is closest to the real cost to the goal $h^*(n)$.

Satisficing Search: Weighted A* Search

- Often it is sufficient to find a "good enough" solution if it can be found very quickly or with way less computational resources. I.e., expanding fewer nodes.
- We could use inadmissible heuristics in A* search (e.g., by multiplying h(n) with a factor W) that sometimes overestimate the optimal cost to the goal slightly.
 - 1. It potentially reduces the number of expanded nodes significantly.
 - 2. This will break the algorithm's optimality guaranty!

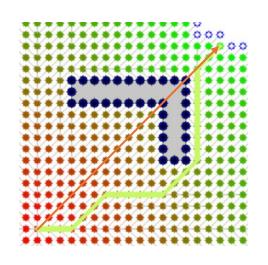

$$\mathrm{f}(n) = g(n) + W \times h(n)$$
 Weighted A* search:
$$g(n) + W \times h(n) \qquad \qquad (1 < W < \infty)$$

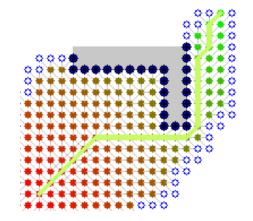

The presented algorithms are special cases:

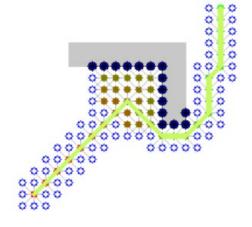

A* search:
$$g(n) + h(n)$$
 $(W = 1)$ Uniform cost search/BFS: $g(n)$ $(W = 0)$ $(W = \infty)$

Example of Weighted A* Search

Reduction in the number of expanded nodes

Breadth-first Search (BFS)
$$f(n) = \#$$
 actions to reach n

Exact A* Search
$$f(n) = g(n) + h_{Eucl}(n)$$

Weighted A* Search
$$f(n) = g(n) + 5 h_{Eucl}(n)$$

Source and Animation: Wikipedia

Summary: All Search Strategies

b: maximum branching factor of the search tree

d: depth of the optimal solution

m: maximum length of any path in the state space

C*: cost of optimal solution

Algorithm	Complete?	Optimal?	Time complexity	Space complexity
BFS (Breadth- first search)	Yes	If all step costs are equal	$O(b^d)$	$O(b^d)$
Uniform-cost Search	Yes	Yes	Number of nodes with $g(n) \leq C^*$	
DFS	In finite spaces (cycles checking)	No	$O(b^m)$	0(bm)
IDS	Yes	If all step costs are equal	$O(b^d)$	O(bd)
Greedy best- first Search	In finite spaces (cycles checking)	No	Depends on heuristic Best case: $O(bd)$ Worst case: $O(b^m)$	
A* Search	Yes	Yes V	Number of nodes with $\begin{array}{c} \text{Number of nodes with} \\ \text{Vith a good heuristic} \\ g(n) + h(n) \leq C^* \end{array}$	

Implementation as Best-First Search

- All discussed search strategies can be implemented using Best-first search.
- Best-first search expands always the node with the minimum value of an evaluation function f(n).

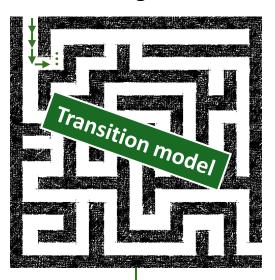

Search Strategy	Evaluation function $oldsymbol{f}(oldsymbol{n})$	
BFS (Breadth-first search)	g(n) (=uniform path cost)	
Uniform-cost Search	g(n) (=path cost)	
DFS/IDS (see note below!)	$\frac{-g(n)}{}$	
Greedy Best-first Search	h(n)	
(weighted) A* Search	$g(n) + W \times h(n)$	

• Important note: Do not implement DFS/IDS using Best-first search! You will get poor space complexity from BFS and the disadvantages of DFS (not optimal and worse time complexity).

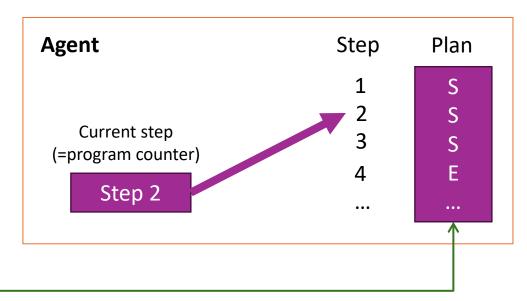

A Planning Agent: Planning vs. Execution Phase

- 1. Planning is done by a planning function using search. The result is a plan.
- 2. The plan can be executed by a **model-based agent function.** The plan + a step counter are stored as the state. The agent function returns the actions from the plan step-by-step.

Planning function

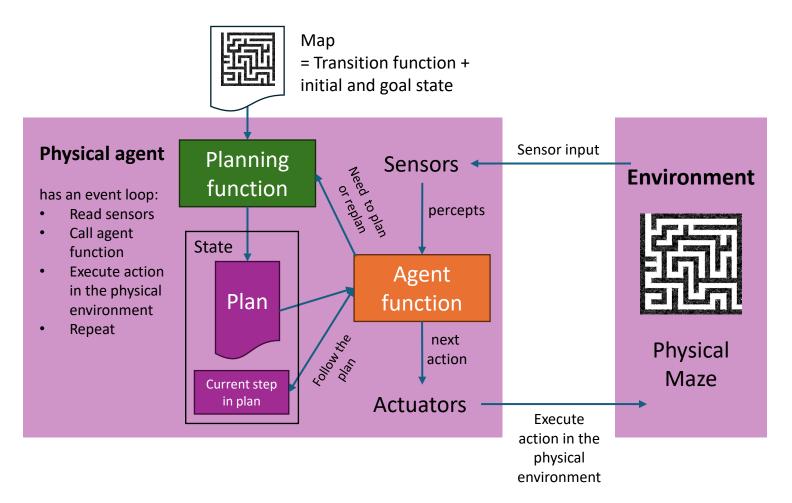

Execution of the plan at step 2 returns action S

Note: The execution agent does not use percepts or the transition function. It blindly follows the plan.

Caution: This only works in an environment with **deterministic transitions**.

Complete Planning Agent to Solve a Maze

- The event loop calls the agent function for the next action.
- The agent function follows the plan or calls the planning function if there is no plan yet or it thinks the current plan does not work based on the percepts (replanning).
